ABSTRACT:
In this experimental study, it was clarified the structural performance of reinforced concrete (RC) and precast concrete (PCa) columns with ultra-high-strength materials. Anti-symmetrical cyclic lateral loads and varying axial loads corresponding to the axial load acting on the exterior column in lower story were applied to the column specimens. The alternative of the design standard strength (F_c) of the concrete is 80 MPa and 120 MPa, and the nominal yield strength of the main reinforcing bar is 490 MPa and 685 MPa. The nominal yield strength of shear reinforcement in a column is 1275 MPa. The six column specimens were manufactured with the combinations of such materials.

The flexural capacity obtained from the experiment was evaluated using the equation of Building Code and Commentary ACI 318-02(2002), and it was found that the equation overestimated the flexural capacity for the F_c 120 MPa specimen. Therefore, the flexural capacity of each specimen was reevaluated using rectangular stress blocks designed for high-strength concrete.

KEYWORDS: ultra-high-strength material, reinforced concrete column, precast concrete column, varying axial load, flexural performance, evaluation of capacity.

1. INTRODUCTION
In recent years, RC buildings are becoming super-high-rise and long-span structures. In such buildings, the columns of the lower stories are subjected to large long-term axial loads. Moreover, when an earthquake occurs, a large varying axial load acts on the exterior columns. Therefore, it is necessary to use higher strength concrete and reinforcing bars, and also the use of more PCa members to rationalize the construction of such super-high-rise buildings in shorter work periods is inevitable.

Six specimens which consist of RC and PCa columns, were manufactured by combining concrete design nominal strength (F_c) 80 MPa and 120 MPa, nominal yield strength of the longitudinal reinforcements 490 MPa (SD490) and 685 MPa (USD685), and nominal yield strength of shear reinforcement 1275 MPa (SBPD1275). This study aimed to clarify the flexural performance of column members made of ultra-high-strength materials by conducting a static bending shear force test on specimens of external columns in the lower stories subjected to varying axial load.
Furthermore, the flexural capacity obtained from the experiment was evaluated to determine whether or not the rectangular stress block method in accordance with the equation of Building Code and Commentary ACI 318-02 (2002), which was designed for normal-strength concrete, is applicable to high-strength concrete such as the specimens used in this study.

2. EXPERIMENTAL PROGRAM
2.1. Description of Specimens
Table 2.1 shows the structural specifications of each specimen. The six specimens have an area of 330 (width:
b) x 330 (overall depth: D) (mm) which is equivalent to 1/3 of the actual column cross-sectional area and a shear span ratio \( (M/V\cdot D) \) of 2.0 in consideration of flexural failure. As shown in Table 2.1, the specimens are roughly divided into three specimens of \( F_c \) 80 MPa and another three specimens of \( F_c \) 120 MPa. The values of longitudinal reinforcements 16-D22(# 7) (Grade: SD490) and 16-D19(# 6) (Grade: USD685) for monolithic cast RC column members with respect to each \( F_c \) value, and full-PCa column members of the latter value of 16-D19 (USD685) were taken into consideration as the variable factors of the specimens. Four of the 16 longitudinal reinforcements are core reinforcing bars for use in exterior columns in the lower stories. The lateral ties (hoops), used commonly in all the specimens, were small-diameter deformed PC steel bars arranged in a single-stroke enclosed lattice pattern.

The specimens ‘C80D22’ and ‘C80D19’ shown in Table 2.1 have different ratios of total area of longitudinal reinforcements to the gross area of column concrete cross-section \( (A_s/A_g) \) but their calculated flexural strengths are almost the same. On the other hand, the specimen ‘PC80D19’ uses a mortar-filled splice sleeve joint to join the longitudinal reinforcements in both column base and capital. The hoops used in these joint sections are the same as those used in other sections. The specimens ‘C120D22’, ‘C120D19’ and ‘PC120D19’ have the same structural specifications as the specimens ‘C80D22’, ‘C80D19’, and ‘PC80D19’ respectively, except for their \( F_c \) being 120 MPa. Figure 2.1 shows the shapes of specimens and their bar arrangement.

Table 2.1 shows the mechanical properties of the reinforcements used in this experiment. Table 2.3 shows the mechanical properties of the concrete. The concrete materials for the specimens include high-early-strength Portland cement for \( F_c \) 80 MPa and normal Portland cement for \( F_c \) 120 MPa with about 10 WT% of silica fume as admixture. Crushed stones having the maximum diameter of 13 mm were used as coarse aggregate for all.

2.2. Test Setup and Loading Sequence

For loading specimens, an L-shaped loading beam as shown in Figure 2.2 was used. While varying axial load was applied to the specimen, anti-symmetric static bending shear force, with the center level of the clear height being the point of contraflexure, was also applied to the specimen repeatedly, with positive and negative horizontal shear forces applied alternately.

Figure 2.3 shows the loading method of varying axial load, where the compressive axial load is expressed as positive load. First, long-term compressive axial load of \(0.2F_{cb}D\) was applied. Then, axial load \(P\) was gradually changed in accordance with the horizontal shear force \(V\). The upper limit and lower limit of the axial load were the compressive axial load \(0.55F_{cb}D\) (\(0.50F_{cb}D\) in the case of \(F_c = 120\) MPa) in positive shear force loading and the tensile axial load \(-0.7A_{st}f_y\) (\(A_{st}f_y\): product of the total area of the longitudinal reinforcements and the actual yield strength) in negative shear force loading. The axial load was kept constant thereafter.

The horizontal shear force was controlled on the basis of story drift angle \((R = \delta/h, \delta\text{ relative horizontal displacement between upper and lower stubs, } h:\text{clear height of column})\). The experiment was terminated after applying shear force once at \(R = \pm 2.5/1000\), twice at \(R = \pm 5/1000, \pm 10/1000, \pm 15/1000, \text{ and } \pm 20/1000\), and once at \(R = \pm 30/1000\) and \(\pm 50/1000\) respectively.
3. DISCUSSION OF TEST RESULTS

3.1. Outline of the Results

Figure 3.1 shows the relationship between the shear force ($V$) and story drift angle ($R$) of all specimens with $P-\Delta$ effect taken into consideration. The single-dot chained lines in the Figure 3.1 represent the proof strength in the case where the hysteretic curve with $P-\Delta$ effect taken into consideration is lowered to a level that is 95% of the maximum shear force. Table 3.1 shows the shear strength and story drift angle of each loading. The shear strength values in the Table 3.1 are those with $P-\Delta$ effect taken into consideration, except for the “first cracking”.

Photo 3.1 shows the final conditions ($R = \pm 50/1000$) of the specimens. The failure patterns shown in Photo 3.1 show flexural crushing in the column capital and column base of the specimens. With the PCa column specimens ‘PC80D19’ and ‘PC120D19’, the degree of shear cracking in the central area of the test section and crushing from the joints to the positions just above the joints was remarkable. However, no such phenomena as buckled longitudinal reinforcements and rupture of hoops were observed in any specimen.

Figure 3.1  Relationship between the shear force ($V$) and story drift angle ($R$).
3.2. Strains in Axial Direction

Figure 3.2 shows the relationship between the axial strain and story drift angle of each specimen. For the expression of the axial strains, the elongation displacement between upper and lower stubs at the axial position in the column was divided by the clear height of column \((h)\) and the tensile strain was expressed as a positive value. The strain performance in the axial direction of the \(F_{c} 80\) MPa and \(F_{c} 120\) MPa specimens while applying tensile axial load remained almost the same. The axial strains of the \(F_{c} 120\) MPa specimen during the large deformation period at and after \(R = +10/1000\) in compressive axial load application mode became large. Also from the appearance of final condition shown in Photo 3.1, it is clear that the degree of crushing in the \(F_{c} 120\) MPa specimen is larger than that in the \(F_{c} 80\) MPa specimen, together with spalling of cover concrete over a larger surface area of the \(F_{c} 120\) MPa specimen.

According to the equation of Building Code and Commentary ACI 318-02 (2002), the axial compressive capacity of a column member using normal-strength concrete is given by the following Eqn. 3.1.

\[
P_0 = 0.85 f_{c}' (A_g - A_o) + A_o f_y
\]  

(3.1)

In connection with Eqn. 3.1 above, Ozbakkaloglu and Saatcioglu (2004) proposed the following equation as an axial compressive capacity expression applicable to a column using concrete of strengths from normal to high-strength level (120 MPa).
Table 3.2 shows the axial compressive capacity of each specimen obtained by using Eqs. 3.1 and 3.2. The rate of loaded axial force, which is obtained by dividing the compressive axial load \( P \) applied to each specimen by the product of the compressive strength of concrete \( (f'_c) \) and total cross-sectional area of the column \( (A_g) \), is slightly larger in the \( F_c 80 \) MPa specimen than in the \( F_c 120 \) MPa specimen. However, calculation of the ratios of axial compressive capacity \( (P_0) \), based on Eqs. 3.1 and 3.2, to the loaded axial force \( (P) \) resulted in a clearly greater ratio for the \( F_c 120 \) MPa specimen in Eqn. 3.2 than in Eq. 3.1 of ACI 318-02 (2002). It is safe to assume that this greater ratio caused the increase in the axial strains of the \( F_c 120 \) MPa specimen during the large story drift angle. There was no difference in the axial strains between RC column specimens prepared by monolithic casting and PCa column specimens.

![Figure 3.2](image-url)  
**Figure 3.2** Relationship between the strain in the axial direction and story drift angle.
The coefficients $\alpha_1$ and $\beta_1$ represented by both (i) and (ii) at a compressive strength of concrete $f'_c \geq 30$ MPa are shown below. The ultimate compressive strain at extreme fiber ($\varepsilon_u$) is 0.003 in common.

\[
\begin{align*}
\alpha_1 &= 0.85 \\
\beta_1 &= 0.85 - 0.008 (f'_c - 30) \geq 0.65
\end{align*}
\]

(ii) Equation proposed by Ozbakkaloglu and Saatcioglu (2004)

\[
\begin{align*}
\alpha_1 &= 0.85 - 0.0014 (f'_c - 30) \geq 0.72 \\
\beta_1 &= 0.85 - 0.0020 (f'_c - 30) \geq 0.67
\end{align*}
\]

The experimental shear strength values of both the first and second peak were evaluated with respect to the case where $P$-$\Delta$ effect was taken into consideration as well as the case where $P$-$\Delta$ effect was not taken into consideration. According to Table 4.1, the experimental shear strength values of both the first and second peak of $F_c$ 80 MPa specimens are higher than the calculated values determined by Eqns. (i) and (ii) even in the case where $P$-$\Delta$ effect is not taken into consideration. Because the calculated shear strength values determined by Eqns. (i) and (ii) were based on the assumption that $\varepsilon_u$ is 0.003 equally, the shear strength from the first peak, or spalling of the cover concrete, seems to have been included. Table 4.1 also indicates that the calculated values of the specimens ‘C80D22’ and ‘C80D19’ are almost equal to the experimental values of shear strength during the first peak. The experimental shear strength values rose thereafter, too. This means that the second peak, or the shear strength under the maximum load, has a safety factor that is about 1.2 times the values calculated from Eqns. (i) and (ii), even in the case where $P$-$\Delta$ effect is not taken into consideration and that the equations can be employed in the structural design.

Regarding the $F_c$ 120 MPa specimens, the experimental shear strength values during the first and second peak, on the basis of the values calculated by Eqn. (i) of Building Code and Commentary ACI 318-02 (2002), cannot be evaluated to be on the safe side. In Eqn. (ii) proposed by Ozbakkaloglu and Saatcioglu (2004), the coefficients $\alpha_1$ and $\beta_1$ of the Eqn. (i) are modified so that the equation can be applied to concrete columns of strengths from normal to high-strength. Using this Eqn. (ii), the experimental shear strength values during the first and second peak of $F_c$ 120 MPa specimens can be evaluated to be nearly on the safe side. However, the safety factor of the experimental shear strength values for $F_c$ 120 MPa specimens during the second peak is comparatively low with respect to that of $F_c$ 80 MPa specimens.

$V_{ACI}$ = flexural capacity calculated by Equation of ACI 318-02 (2002)

$V_{HSC}$ = flexural capacity calculated by Equation of Ozbakkaloglu and Saatcioglu (2004)
It is assumed that the ultimate compressive strain at extreme fiber ($\varepsilon_{u}$) is 0.003 in the flexural capacity calculation method using these rectangular stress blocks. This is the reason why it is not suitable for calculating the shear strength during the second peak (flexural capacity) where the high-strength longitudinal reinforcements of a column undergo compressive yield phenomenon as observed in this study.

5. CONCLUSIONS

A bending shear force test was conducted on RC and PCa columns with ultra-high-strength materials subjected to varying axial load, and the following findings were obtained:
1. With almost equal calculated flexural strength provided for specimens with longitudinal reinforcements D22(# 7) (SD490) and D19(# 6) (USD685), the former developed spalling of cover concrete immediately after the compressive yield of longitudinal reinforcements, while the latter first developed spalling of cover concrete and then compressive yield of longitudinal reinforcements.
2. Specimens with a concrete design nominal strength of $F_c$ 80 MPa and $F_c$ 120 MPa were subjected to a load of compressive axial force of 0.55$F_c b D$ and 0.50$F_c b D$ respectively. The axial strains during large story drift angle in the $F_c$ 120 MPa specimen was larger than that in the $F_c$ 80 MPa specimen, while spalling of cover concrete developed widely in the $F_c$ 120 MPa specimen.
3. PCa column specimens of both $F_c$ 80 MPa and $F_c$ 120 MPa indicated larger shear strength during cover concrete spalling than RC column specimens. On the contrary, an increase in shear strength thereafter was small. The maximum shear strength of PCa column specimens was also a little lower than that of the RC column specimens prepared by monolithic casting.
4. The flexural capacity of each specimen was evaluated by the rectangular stress block method in compliance with Building Code and Commentary ACI 318-02 (2002). The flexural capacity levels obtained with $F_c$ 80 MPa specimens were largely on the safe side, whereas those obtained with $F_c$ 120 MPa were not necessarily on the safe side. However, it was confirmed that the experimental values were considered to be on the safe side by applying the stress blocks in accordance with the proposal of Ozbakkaloglu and Saatcioglu (2004) to the evaluation.

NOTATION

$A_c$ = area of core concrete within perimeter hoop (center-to-cente), $A_g$ = gross area of column cross-section, $A_{lr}$ = total area of longitudinal reinforcement, $b$ = width of a column cross-section, $D$ = overall depth of a column cross-section, $F_c$ = design nominal strength of concrete, $f_c'$ = concrete cylinder compressive strength, $f_y$ = yield strength of longitudinal reinforcement, $P$ = axial load, $P_0$ = nominal concentric compressive capacity of a column calculated according to Eqn. 3.1, $P_{0(HSC)}$ = nominal concentric compressive capacity of a column using concrete of strength from normal to high strength level (120 MPa) calculated according to Eqn. 3.2, $\alpha_1$ = coefficient that defines width of rectangular stress block, $\beta_1$ = coefficient that defines height of rectangular stress block, $\varepsilon_{u}$ = extreme compression fiber strain in concrete at ultimate moment resistance, $\gamma$ = coefficient defined in Eqn. 3.4
